# Supersymmetry and the Standard Model

The fundamental theory of particle physics, known as the Standard Model (SM) can predict precise interactions between the fundamental particles in our universe. With these predictions we can confirm processes, but there are some aspects of the universe that have not yet been explained. In this Chapter, we will analyze the Standard Model, look at some specific shortcomings, and introduce supersymmetry as a possible solution.

### 2.1 The Standard Model

After decades of theoretical and experimental research the SM has been developed into a theory that explains the Electromagnetic (EM), Strong, and Weak forces. The SM has not yet been able to include Gravity within the theory. With the robust theoretical and experimental methods used in the SM, we have discovered new elementary particles and predicted others.

#### 2.1.1 The Fundamental Particles

All visable matter can be explained by three kinds of elementary particles: leptons, quarks, and gauge bosons. Each of these can be distinguished by various quantum properties. The leptons and quarks are fermions, which are particles that have half-integer spin. Leptons are particles that only interact with the EM and

Weak force, while quarks interact with all three forces of the SM. The gauge bosons are the force carries for each respective force and have integer spin.

There are three generations of leptons and quarks which are differentiated by a charge  $\pm e$ , the charge of an electron. Leptons have three different charged particles: electron (e), muon  $(\mu)$ , and tau  $(\tau)$ , with each charged particle having a corresponding neutrino  $(\nu)$  of the same flavor, see fig 2.1. Quarks are also separated into three generations of doublets, the down-type  $(-\frac{1}{3}e)$ : down (d), strange (s), and bottom (b) and up-type  $(\frac{2}{3}e)$ : up (u), charm (c), and top (t), see fig 2.1. Each of the quarks has a color associated with it which is analogous to an electric charge, except there are three colors charges: red, blue, and green.

### 2.1.2 Quantum Field Theory

The interactions of all these particles are described by quantized fields whose operators describe the creation and annihilation of particles. Each of the fields of the SM have a corresponding gauge boson, see fig. 2.1. The most well-known being the EM field and its interactions. In order to write a concise theory of the particles in the SM, the symmetry and conservation laws of the SM can be derived by starting with Noether's Theorem.

#### 2.1.3 Noether's Theorem

Noether's theorem states, "to each symmetry of a local Lagrangian, there corresponds a conserved current". This can be done by allowing for an infinitesimal symmetry variation. Requiring the Lagrangian to be invariant under  $\phi(x) \to \phi'(x) = \phi(x) + \alpha \Delta \phi(x)$ , where  $\alpha$  is infinitesimal real parameter and  $\Delta \phi$  is a deformation to

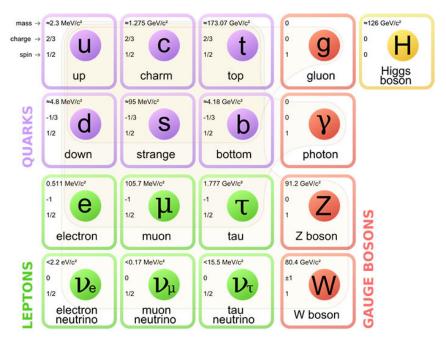

Figure 2.1: The fundamental particles of the Standard Model. There are three generations of quarks and leptons. Along with the five bosons, where four of them relate to the interactions of the three forces included in the SM: Electromagnetism, the Weak force, and the Strong force and the final being the Higgs boson.

the field, up to a 4-divergance, the Lagrangian transforms as,

$$\mathcal{L}(x) \to \mathcal{L}(x) + \alpha \partial_{\mu} \mathcal{J}^{\mu}(x),$$
 (2.1)

where  $\mathcal{J}^{\mu}$  is a current. If we apply the Euler-Lagrange equation,

$$\partial_{\mu} \left( \frac{\partial \mathcal{L}}{\partial (\partial_{\mu} \phi)} \right) - \frac{\partial \mathcal{L}}{\partial \phi} = 0,$$
 (2.2)

to Eqn. 2.1 with the addition of the fluctuation of the particle field. After some simplification we get a conserved current [1,2],

$$\partial_{\mu}j^{\mu}(x) = 0$$
, where  

$$j^{\mu}(x) = \frac{\partial \mathcal{L}}{\partial(\partial_{\mu}\phi)}\Delta\phi - \mathcal{J}^{\mu}.$$
(2.3)

We see from the above equation that the current  $j^{\mu}(x)$  of the Lagrangian is conserved. Now let's apply this to the particle fields of the SM.

#### 2.1.4 Quantum Electrodynamics (QED)

First, we start with the assumption that the wave function  $\psi(x)$  should transform as,

$$\psi(x) \to e^{i\alpha(x)}\psi(x),$$
 (2.4)

where  $\alpha(x)$  has an arbitrary dependence on space and time. If one were to include this into the Lagrangian for a spin-1/2 particle in a vacuum,

$$\mathcal{L}_{QED}^{vac} = i\overline{\psi}\gamma^{\mu}\partial_{\mu}\psi - m\overline{\psi}\psi \tag{2.5}$$

Type	Form	Components	Space Inversion
Scalar	$\overline{\psi}\psi$	1	+ under $P$
Vector	$\overline{\psi}\gamma^{\mu}\psi$	4	Space compts.: $-$ under $P$
Tensor	$\overline{\psi}\sigma^{\mu\nu}\psi$	6	
Axial Vector	$\overline{\psi}\gamma^5\gamma^\mu\psi$	4	Space compts.: $+$ under $P$
Pseudoscalar	$\overline{\psi}\gamma^5\psi$	1	- under $P$

Table 2.1: A table showing all forms of the fermion currents. These can be symmetric under parity transformation in all or some components.

where the  $\gamma^{\mu}$  are the Dirac matrices,  $\partial_{\mu}$  is the partial derivative,  $\overline{\psi}$  is the hermitian conjugate of the wavefuntion  $\psi$ , and m is the mass of the particle. As a small aside, the bilinear quantities  $\overline{\psi}(4\times4)\psi$  have certain properties under lorentz transformations when the  $4\times4$  matrix is a  $\gamma$ -matrices. These are of the form,

$$\gamma^{0} = \begin{bmatrix} \mathbf{I} & 0 \\ 0 & -\mathbf{I} \end{bmatrix}, \boldsymbol{\gamma} = \begin{bmatrix} 0 & \boldsymbol{\sigma} \\ -\boldsymbol{\sigma} & 0 \end{bmatrix}, \gamma^{5} = \begin{bmatrix} 0 & \mathbf{I} \\ \mathbf{I} & 0 \end{bmatrix}$$
(2.6)

where the I is the identity matrix and  $\sigma$  are the Dirac matrices. We can combine the first two parts of Eqn. 2.6 and write it compactly as  $\gamma^{\mu}$  where  $\mu = 0, 1, 2,$  and 3. The possible interesting quantities of the above transformations are shown in Table 2.1.

To allow for the field to be invariant, we must include a derivative,  $D_{\mu}$ , that is covariant under phase transformations,

$$D_{\mu} \equiv \partial_{\mu} - ieA_{\mu}. \tag{2.7}$$

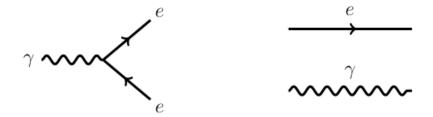

Figure 2.2: The possible feynman diagrams in QED. The e can be replaced with any spin-1/2 charged particle. We see that the electron and photon can propagate freely in space or a vertex with one photon and a particle-antiparticle pair is allowed.

The covariant derivative includes the vector field  $A_{\mu}$  which must also transform as,

$$A_{\mu} \to A_{\mu} + \frac{1}{e} \partial_{\mu} \alpha.$$
 (2.8)

So after requiring that there be a local gauge transformation, we were forced to introduce a vector field  $A_{\mu}$ , called the gauge field, which couples to Dirac particles in the same way as the photon field. We will think of this new field as the real photon field, which means we need to add a kinematic energy portion to the lagrangian. This kinematic term will be invariant under Eqn. 2.8, which leads us to final representation of the QED lagrangian which can be written down concisely as,

$$\mathcal{L}_{QED} = \overline{\psi}(i\gamma^{\mu}\partial_{\mu} - m)\psi + e\overline{\psi}\gamma^{\mu}A_{\mu}\psi - \frac{1}{4}F^{\mu\nu}F_{\mu\nu}, \qquad (2.9)$$

where  $A_{\mu}$  is the EM field operator and  $F^{\mu\nu}$  is the EM field tensor. This Lagrangian describes the interactions between spin-1/2 charged particles and the U(1) EM force. Each of the parts of this equation are lorentz invariant which allows this to be true in all reference frames.

From the QED Lagrangian Eqn. 2.9, we see that particles that interact electro-

magnetically can interact with the photon. This can be shown as a feynman diagram, see Fig. 2.2, which has a vertex interaction with a photon and a particle-antiparticle pair. These, and the inclusion of freely moving particles, are the basic types of feynman diagrams for QED.

#### 2.1.5 Quantum Chromodynamics

Let's now transition from the description of the U(1) EM field to the SU(3) Quantum Chromodynamic (QCD) field and the transformation of quark fields. A quark in a vaccuum is described by,

$$\mathcal{L}_{QCD}^{vac} = \overline{q}_j (i\gamma^{\mu}\partial\mu - m)q_j, \qquad (2.10)$$

where  $q_1, q_2$ , and  $q_3$  are the three color fields. From this we want to require that the field is again invariant under another local phase transformation such as,

$$q(x) \to Uq(x) \equiv e^{i\alpha_a(x)T_a}q(x),$$
 (2.11)

where U is a  $3\times3$  unitary matrix,  $T_a$  with  $a=1,\ldots,8$  are a set of linearly independent traceless  $3\times3$  matrices, and  $\alpha_a$  are the group parameters. Since the generators  $T_a$  do not necessarily commute with each other, we can see that it is a non-Abelian transformation and the commutator can be represented as,

$$[T_a, T_b] = i f_{abc} T_c, \tag{2.12}$$

where  $f_{abc}$  are constants.

We need to impose SU(3) local gauge invariance on Eqn. 2.10, to allow for the

following phase transformations,

$$q(x) \to (1 + i\alpha_a(x)T_a)q(x),$$

$$\partial_{\mu}q \to (1 + i\alpha_aT_a)\partial_{\mu}q + iT_aq\partial_{\mu}\alpha_a.$$
(2.13)

From this is seems straight forward that we can proceed in exactly the same manner as QED, which is to add a transformation to the derivative,

$$D_{\mu} = \partial_{\mu} + ig_{\mathcal{O}} T_a G_{\mu}^a. \tag{2.14}$$

where the field  $G^a_\mu$  transforms as,

$$G^a_\mu \to G^a_\mu - \frac{1}{g_Q} \partial_\mu \alpha_a,$$
 (2.15)

where  $g_Q$  is the coupling strength of QCD interactions. This will give us a similar Lagrangian to the QED one described above, but this is not sufficient for a non-Abelian gauge transformation and it does not produce a gauge-invariant Lagrangian. One final transformation is required for the  $G^a_\mu$  fields,

$$G^a_\mu \to G^a_\mu - \frac{1}{g_Q} \partial_\mu \alpha_a - f_{abc} \alpha_b G^c_\mu.$$
 (2.16)

This finally gives us a gauge invariant kinetic energy term for all the  $G^a_{\mu}$  fields and thus we can write the QCD interactions as,

$$\mathcal{L}_{QCD} = \overline{q}(i\gamma^{\mu}\partial_{\mu} - m)q - g_{Q}(\overline{q}\gamma^{\mu}T_{a}q)G_{\mu}^{a} - \frac{1}{4}G_{\mu\nu}^{a}G_{a}^{\mu\nu}.$$
 (2.17)

From the QCD Lagrangian Eqn. 2.17, we can see that it includes all of the same interactions we showed for QED, but must be color neutral. However, QCD also

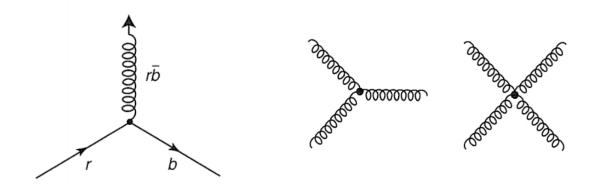

Figure 2.3: The possible feynman diagrams in QCD. Each vertex needs to be color neutral. Here is just an example of a red-blue vertex. QCD also includes a 3- and 4-vertex with gluons.

included a 3- and 4-vertex interaction between the gluons, which arises due to the non-abelian nature of the force. From this, it is easy to tell that QCD is a much more complicated theory. We seem to be missing a vital part of the SM, specifically a theory for the Weakly interacting processes which is mediated by the massive bosons, W and Z from fig. 2.1.

### 2.1.6 Weak Force

The Weak force is responsible for nuclear decay. The Weak force has an interaction of the type  $\frac{1}{2}\gamma^{\mu}(1-\gamma^5)$  so it is a V-A interaction with SU(2) symmetry. From this, we can conclude that it violates Parity. Parity is a transformation from  $(x,y,z) \to (-x,-y,-z)$  or space inversion. Since it violates Parity, the next step is to consider a conservation of CP, where C is charge conjugation (particle-to-antiparticle).

The main experimental implications of this proposed conservation comes from the decay of the neutral Kaon,  $K^0(\overline{s}d)$  and  $\overline{K}^0(s\overline{d})$ . These have two CP states which are,

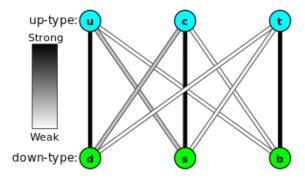

Figure 2.4: A gramatical representation to show the couplings for Weak interactions, known as the Cabibbo-Kobayashi-Maskawa Matrix.

 $CP|K^0\rangle = -|\overline{K}^0\rangle$ , and  $CP|\overline{K}^0\rangle = -|K^0\rangle$ . Once we normalize these eigenstates of CP we get the corresponding wavefunctions,

$$|K_1\rangle = \left(\frac{1}{\sqrt{2}}\right)(|K^0\rangle - |\overline{K}^0\rangle) \text{ and } |K_2\rangle = \left(\frac{1}{\sqrt{2}}\right)(|K^0\rangle + |\overline{K}^0\rangle),$$
 (2.18)

where each has the invariance  $CP|K_1\rangle = |K_1\rangle$  and  $CP|K_2\rangle = -|K_2\rangle$ . The two Kaon states are expected to decay into either two pions or three pions for  $|K_1\rangle$  and  $|K_2\rangle$ , respectively. Since there is a greater energy release in the  $|K_1\rangle$  state the lifetime of that particle is thought to be less than  $|K_2\rangle$ . After experimenting on the purity of Kaon decays after a long distance away from an interaction point, we have found that it is possible for the  $|K_1\rangle$  to decay into three pions. This is direct evidence of Weak decays violating CP conservation.

Now the Weak force is mediated by two vector bosons, W and Z, see fig. 2.1. These are unlike the other forces because these vector bosons have a large mass of  $m_W = 80.379 \pm 0.012$  GeV and  $m_Z = 91.1876 \pm 0.0021$  GeV. The W boson is a charged particle and interacts with many nuclear decays.

The W boson interacts very interestingly for quarks in the SM. There is a mixing of flavors of quarks for particles. They will mix partners between up-type and downtype particles, see fig. 2.4. [Kobayashi, M. and Maskawa, K. (1973) Progress in Theoretical Physics, 49, 652]. The interactions for the generalized three generations of quarks is known as the Cabibbo-Kobayashi-Maskawa (CKM) matrix,

$$\begin{bmatrix} d' \\ s' \\ b' \end{bmatrix} = \begin{bmatrix} V_{ud} & V_{us} & V_{ub} \\ V_{cd} & V_{cs} & V_{cb} \\ V_{td} & V_{ts} & V_{tb} \end{bmatrix} \begin{bmatrix} d \\ s \\ b \end{bmatrix}, \qquad (2.19)$$

where for example,  $V_{ud}$  is the coupling of u to d which is exactly  $(d \to u + W^-)$ . This matrix can be reduced to a form which has three generalized Cabibbo angles  $(\theta_{12}, \theta_{23}, \theta_{13})$  and a phase factor  $(\delta)$ . The coupling between the third generation does not mix with the other two generations. From that we can recover the Cabibbo-GIM matrix[cite here]. For the moment, we can only determine these values from experimentation.

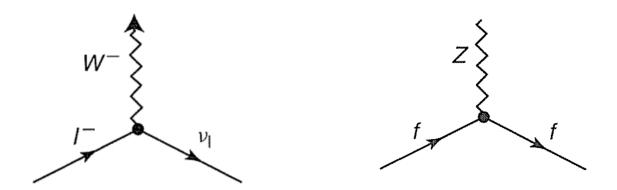

Figure 2.5 : Feynman diagram for Neutral Weak interaction and the charged weak current.

The Z boson is known as the neutral current. This boson mediates forces between particles and their respective antiparticles, see fig. ??. This interaction for the neutral weak force is  $\gamma^{\mu}(c_V^f - c_A^f \gamma^5)$  which is quite similar to the charged weak interaction, but differs by the constants  $c_V^f$  and  $c_A^f$ . The Weak interactions are shown in Fig. 2.5. We see the charged W boson interactions with the charged leptons and their respective neutrinoes or allows for flavor changing interactions with quarks. The neutral Z boson interacts in the same way as the photon.

#### 2.1.7 The Electroweak Lagrangian

The simplest group for the Electroweak interaction is  $SU(2)_L \times U(1)_Y$  which will give the left-handed interactions in doublets with the addition of massive gauge bosons W and Z with a massless photon. We first consider the free Lagrangian,

$$\mathcal{L} = \overline{\psi}_j \gamma^\mu \psi_j, \tag{2.20}$$

where j is the fermion wavefunction. We are not including the mass parameter because it would cause the left and right-handed parts to mix. This is assumed to transform under the global invariant

$$\chi_L \to \chi_L' = e^{i\frac{\tau_a}{2}\alpha^a(x) + i\beta(x)Y} \chi_L,$$

$$\psi_R \to \psi_R' = e^{i\beta(x)Y} \psi_R$$
(2.21)

where the transformation  $e^{i\frac{\tau_a}{2}\alpha^a(x)}$  with a=1,2,3 is the  $SU(2)_L$  transformation and only acts on the left-handed doublet. The next step is to require that the Lagrangian is invariant under local  $SU(2)_L \times U(1)_Y$ . We allow for the following

covariant derivatives,

$$D_{\mu}\psi_{1} = [\partial_{\mu} - ig_{W}\frac{\tau_{a}}{2}W_{\mu}^{a} - ig_{W}'y_{1}B_{\mu}]\psi_{1}$$

$$D_{\mu}\psi_{2} = [\partial_{\mu} - ig_{W}'y_{2}B_{\mu}]\psi_{2}$$

$$D_{\mu}\psi_{3} = [\partial_{\mu} - ig_{W}'y_{3}B_{\mu}]\psi_{3}$$
(2.22)

where  $g_W$  and  $g'_W$  are the Weak force coupling constants while  $W^a_\mu$  and  $B_\mu$  are four gauge bosons and can be the possible candidates for  $W^\pm$ , Z and  $\gamma$ .

Just like the above descriptions the fields need to transform along with the wavefuntions and derivatives. These transformations are,

$$B_{\mu} \to B'_{\mu} = B_{\mu} + \frac{1}{g'_W} \partial_{\mu} \beta(x)$$

$$W \mu \to W'_{\mu} = U_L W_{\mu} U_L^{\dagger} - \frac{1}{g_W} \partial_{\mu} U_L U_L^{\dagger}$$
(2.23)

where  $U_L = e^{i\frac{\tau_a}{2}\alpha^a(x)}$ . These transformation are similar to the QED and QCD transformation. If we include all of these invariant transformations in the free Weak Lagrangian Eqn. 2.20 and we get a free invariant Lagrangian, but this does not allow us to include a mass term for the fermions. Therefore this is not a viable procedure to include the Electroweak interactions into the model. In order to do this we must include the Higgs Mechanism.

#### 2.1.8 The Higgs Mechanism

We are interested in the spontaneous symmetry breaking of a local SU(2) group. Specifically, the following Lagrangian,

$$\mathcal{L} = (\partial_{\mu}\phi)^{\dagger}(\partial^{\mu}\phi) - \mu^{2}\phi^{\dagger}\phi - \lambda(\phi^{\dagger}\phi)^{2}, \tag{2.24}$$

with  $\phi$  being a SU(2) doublet of complex scalar fields,

$$\phi = \frac{1}{2} \begin{bmatrix} \phi_1 + i\phi_2 \\ \phi_3 + i\phi_4 \end{bmatrix}$$
 (2.25)

and is invariant under global SU(2) phase transformations  $\phi \to e^{i\alpha_a \tau_a/2} \phi$ . To allow for local invariance, we first allow for a covariant derivative,

$$D_{\mu} = \partial_{\mu} + ig_W \frac{\tau_a}{2} W_{\mu}^a, \qquad (2.26)$$

where we now have three gauge fields,  $W^a_\mu$ . If we assume an infanitesimal gauge transformation for the SU(2) doublet  $\phi(x) \to \phi'(x) = (1 + i\frac{\tau_a}{2}\alpha^a(x))\phi(x)$ , then the gauge fields will transform as,

$$W_{\mu}^{a} \to W_{\mu}^{a} - \frac{1}{g_{W}} \partial_{\mu} \alpha_{a} - f_{abc} \alpha_{b} W_{\mu}^{c}. \tag{2.27}$$

You can see that Eqn. 2.27 is similar to Eqn. 2.16 where we have replaced the QCD gauge field with the three gauge fields  $W^a_{\mu}$ . If we include these locally invariant transformations into the above SU(2) Lagrangian we get,

$$\mathcal{L} = (\partial_{\mu}\phi + ig_W \frac{1}{2}\tau_a W_{\mu}^a \phi)^{\dagger} (\partial^{\mu}\phi + ig_W \frac{1}{2}\tau_a W^{a\mu}\phi) - \mu^2 \phi^{\dagger}\phi + \lambda(\phi^{\dagger}\phi)^2 - \frac{1}{4}W_{\mu\nu}^a W^{a\mu\nu},$$
(2.28)

where the gauge field kinetic term has been included at the end. The most interesting regions of this Lagrangian is when  $\mu^2 < 0$  and  $\lambda > 0$ , and the potential has a minimum at  $\phi^{\dagger}\phi = -\frac{\mu^2}{2\lambda}$ . With this we will expand the potential around the minimum and require that,

$$\phi_1 = \phi_2 = \phi_4 = 0, \phi_3^2 = -\frac{\mu^2}{2\lambda} \equiv v^2.$$
 (2.29)

This is the spontaneous symmetry breaking of the SU(2) symmetry, because of this we are able to substitute an expansion for the field,

$$\phi = \sqrt{\frac{1}{2}} \begin{bmatrix} 0 \\ v + h(x) \end{bmatrix} \tag{2.30}$$

with this specific transformation of the SU(2) doublet and the simplification of Eqn. 2.28, the only remaining field is h(x) which is referred to as the Higgs field. This is what is known as the Higgs Mechanism for a SU(2) symmetry.

#### 2.1.9 Electroweak

We want to include the Higgs Mechanism into the weak isospin and weak hypercharge,  $SU(2)_L \times U(1)_Y$ , transformations of electoweak interactions. Isospin and hypercharge is defined as  $I_3 = \frac{1}{2}(n_u - n_d)$  and  $Y \equiv B + S$ , respectfully, where  $n_u, n_d$  is the number of up or down quarks, B is the baryon number, and S is the strangeness. The weak isospin triplet for weak currents can be written down using Eqn. 2.28,

$$J_{\mu}^{i}(x) = \overline{\chi}_{L} \gamma_{\mu} \frac{1}{2} \tau_{i} \chi_{L}, \text{ with } i = 1, 2, 3.$$
 (2.31)

Since this is a current we can calculate the charge by integrating of all of space,  $T^i = \int J_0^i(x) d^3x$ , which will give us the generators of the  $SU(2)_L$  symmetry  $[T^i, T^j] = i\epsilon_{ijk}T^k$ . Weak hypercharge, Y, is then defined by  $Q = T^3 + \frac{Y}{2}$  where Q is the charge and  $T^3$  is the third component of the weak isospin. The weak hypercharge is a conserved quantity of the  $U(1)_Y$  symmetry.

First, we need to include the coupling of the Weak current  $J^a_\mu$  and the gauge field  $W^{a\mu}$  such that,

$$-ig_W J^a_\mu W^{a\mu} = -ig_W \overline{\chi}_L \gamma_\mu T^a W^{a\mu} \chi_L \tag{2.32}$$

which is the basic interaction for the  $SU(2)_L$  symmetry. Then, we also need to include the weak hypercharge current with the fourth vector boson  $B^{\mu}$ ,

$$-i\frac{g'_{W}}{2}j_{\mu}^{Y}B^{\mu} = -ig'_{W}\overline{\psi}\gamma_{\mu}\frac{Y}{2}\psi B^{\mu}, \qquad (2.33)$$

here the operators  $T^a$  and Y are generators for the  $SU(2)_L$  and  $U(1)_Y$  gauge transformations, respectively. Now we combine the two symmetries with the transformations of the left and right hand components of  $\psi$  and from this we can write down the contributions of the two gauge fields  $W^3_{\mu}$  and  $B_{\mu}$  and the mising angle  $\theta_W$  to find the interactions of the two neutral currents. The physical fields are thus,

$$-ig_W J^3_{\mu} W^{3\mu} - i\frac{g'_W}{2} j^Y_{\mu} B^{\mu} = -iej^{em}_{\mu} A^{\mu} - \frac{ie}{\sin\theta_W \cos\theta_W} [J^3_{\mu} - \sin^2\theta_W j^{em}_{\mu}] Z^{\mu}. \quad (2.34)$$

From this we can write down the Electroweak Lagrangian, for any fermion that interacts with the field. Moreover, we can formulate the Higgs mechanism, such that we can calculate the theoretical masses of the gauge bosons and fermions as,

$$M_W = \frac{1}{2}vg_W M_Z = \frac{1}{2}v\sqrt{g_W^2 + g_W'^2},$$
 (2.35)

but these masses cannot be predicted since they depend on the values from the chosen Higgs field.

#### 2.1.10 The Standard Model Lagrangian

With the inclusion of the Higgs mechanism and the formulation of a local gauge invariant Lagrangian for the Electroweak and QCD fields, we have the complete SM Lagrangian as,

$$\mathcal{L} = -\frac{1}{4}W_{\mu\nu}^{a}W^{a\mu\nu} - \frac{1}{4}B_{\mu\nu}B^{\mu\nu} - \frac{1}{4}G_{\mu\nu}^{a}G_{a}^{\mu\nu} 
+ \overline{L}\gamma^{\mu}(i\partial_{\mu} - g_{W}\frac{1}{2}\tau^{a}W_{\mu}^{a} - g_{W}'\frac{Y}{2}B_{\mu} - g_{Q}T_{b}G_{\mu}^{b})L 
+ \overline{R}\gamma^{\mu}(i\partial_{\mu} - g_{W}'\frac{Y}{2}B_{\mu} - g_{Q}T_{b}G_{\mu}^{b})R 
+ |(i\partial_{\mu} - g_{W}\frac{1}{2}\tau^{a}W_{\mu}^{a} - g_{W}'\frac{Y}{2}B_{\mu})\phi|^{2} - V(\phi) 
- (G_{1}\overline{L}\phi R + G_{2}\overline{L}\phi_{c}R + \text{hermitian conjugate}),$$
(2.36)

where the first terms are the kinetic energies and self-interactions of the  $W^{\pm}$ , Z, g, and  $\gamma$  bosons, the second and third terms are the kinetic energies and interactions of the leptons and quarks with the  $W^{\pm}$ , Z, g, and  $\gamma$  bosons where L is a left-handed fermion doublet and R is a right-handed fermion singlet. The fourth term is the  $W^{\pm}$ , Z,  $\gamma$  and Higgs masses and couplings. The final term is the lepton and quark masses and couplings to the Higgs field.

## 2.2 Fundamental Problems in the Standard Model

The SM is able to accurately and precisely describe many facets of the universe. Whether it comes to predicting the existence of a sixth quark or the confirmation of g-2 for the muon to 9 orders of magnitude. Unfortunately, there is some evidence of matter or interactions that cannot be described such as dark matter, the Hierarchy problem, and a possible grand unified theory. Let's look into each of these further.

#### 2.2.1 Dark Matter

The main motivation for Dark Matter is the difference between the visible matter and the measureable matter in the universe. This has most notably been seen in the

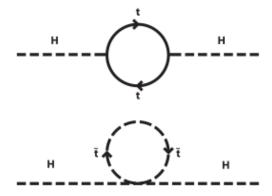

Figure 2.6: The loop corrections to the Higgs boson interacting with a top quark and its superpartner the top squark. This is a next-to-leading order (NLO) correction to the Higgs boson mass.

radial velocities of stars in galaxies. In a galaxy which is solely made up of visible matter, matter that interacts with light, the radial velocity of stars should decrease as  $1/\sqrt{r}$  the further away it is from the galactic nuclei, although measurements show the velocity becoming constant as a function of radius.

The original study of this was from the galaxy NGC 1560, where the measured galactic velocity curve provided a result that was 400 times large than the visible matter in the cluster (A. H. Broeils Astron. and Astrophys. 256 19 (1992)). To reproduce these features in models, the mass of the galaxy must be significantly more than what is seen. This implies some unseen dark matter, that still interacts with the gravitational field but not with the EM field. There is currently no such particle in the SM that has these properties.

#### 2.2.2 Hierarchy Problem

The Higgs boson is a beautiful solution to electroweak symmetry breaking and gives a method for particles to acquire mass, see Sec. 2.1.8, and was discovered to have a measured mass of  $m_H = 125.18 \pm 0.16$  GeV. This value though is not predictable with the SM and leads to some inconsistencies when you include loop corrections. Since the Higgs is strongly coupled to particles with large masses, the dominant loop correction is due to interactions with the t quark. These higher order loop corrections to the Higgs mass,  $m_H^2$ , caused by the fermionic t loop, see fig 2.6, are,

$$\Delta m_H^2 = -\frac{|\lambda_t|^2}{8\pi^2} \Lambda_{UV}^2 + \cdots, \tag{2.37}$$

where  $\lambda_f$  is the vertex factor for the respective fermion and  $\Lambda_{UV}$  is the ultraviolet momentum cutoff. The Higgs boson loop corrections are highly dependent on all virtual and real particles that couple to the Higgs field, we can see the corrections from Eqn. 2.37 from the t quark will cause a large divergence. The quadratic divergence of the Higgs mass is only renormalizable with a fine tuning of the parameters  $\lambda_f$  and  $\Lambda_{UV}$ .

This means the only way for the SM to reconcile this unfortunate fact is to have a relatively lucky cancellation of very large numbers of order 10<sup>32</sup> with equally small numbers. Fortunately, if we add the contribution of a bosonic partner of the fermion the Higgs loop corrections reduce to,

$$\Delta m_H^2 = \frac{\lambda_S}{16\pi^2} [\Lambda_{UV}^2 - 2m_S^2 ln(\Lambda_{UV}/m_S) + \cdots].$$
 (2.38)

With the introduction of a scalar partner to the t, there is a logarithmic divergence to the higgs boson mass and can be renormalized through the normal methods.

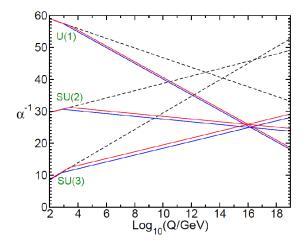

Figure 2.7: The energy dependence of the inverse gauge couple of each force in the SM (dashed line) and the MSSM (solid lines). The MSSM gives two thresholds for the sparticle mass 750 GeV and 2.5 TeV.

#### 2.2.3 Grand Unified Theory

The SM is able to accurately describe three of the fundamental sources at typical energy scales, 1 to  $10^4$  GeV, but idealy the forces would be able to merge into a single force at higher energies. This has not been directly observed, but many theories, such as supersymmetry (SUSY), predict its existence [3].

At standard energies for particle physics experiments the difference in the strength of each force is quite noticeable. But it has been shown that in the SM the strengths of each force are dependent on the energy scale and it would be ideal that they converge to a single force at large energies, such as 10<sup>16</sup> GeV. In fig. 2.7, we see the extrapolated energy scales of the forces in the SM shown as the dotted line. These unfortunately, do not meet at a single point to become one force, but if we include supersymmetry into the model we get a nice convergence between the forces [3].

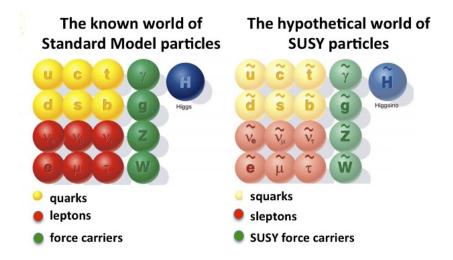

Figure 2.8: The corresponding SUSY particles which are partners to the SM particles.

## 2.3 Supersymmetry

We have seen from the above three problems that there is still more to learn. Some of the features of the universe, such as; dark matter, the hierarchy problem, and a grand unified theory have not been explained. We saw from the Hierarchy problem that the addition of a bosonic partner to a fermion will allow for the loop corrections to be renormalizable without fine tuning. Fortunately, some theories have allowed for such a problem to be solved. Namely the theory of SUSY which essentially states that each particle in the SM has a superpartner that has only the spin changed, that every fermion has a bosonic partner that has all the same quantum numbers except the spins differ by 1/2, and vice-versa.

The partners to the fermions are denoted with a 's' in front of the name to notify that it is the scalar form of the particle and the partners to the bosons have an 'ino' attached at the end, such as photino, gluino, wino, and Higgsino. So for the partners to the fermionic particles in the standard model we have: sup  $(\widetilde{u})$ , sdown  $(\widetilde{d})$ , scharm  $(\widetilde{c})$ , sstrange  $(\widetilde{s})$ , stop  $(\widetilde{t})$ , and sbottom  $(\widetilde{b})$  for the squarks and selectron  $(\widetilde{e})$ , smuon  $(\widetilde{\mu})$ , and stau  $(\widetilde{\tau})$  for the charged sleptons. The partners to the neutrinos, which are always left-handed if you neglect the minimal masses, are sneutrinos  $(\widetilde{\nu}_e, \widetilde{\nu}_\mu, \widetilde{\nu}_\tau)$ , where whe have one for each flavor of lepton, see Fig. 2.8.

If the SUSY was unbroken the superpartners would have exactly the same properties as the SM pairs except their spin. This would cause a massless photino or a  $m_{\tilde{e}} = 0.511$  keV selectron. These particles would certainly have been detected at this point, which leads us to think that SUSY is a broken symmetry where all the superpartners have a mass that is significantly higher than their SM partners.

#### 2.3.1 Supermultiplets and Chirality

A supermultiplets is any symmetry where the number of bosonic degrees of freedom and fermionic degrees of freedom are equal,  $n_B = n_F$ . The simplest way to achieve this is to have a combination of a single Weyl fermion, which is a chiral representation of the fermion and has two spin helicity states,  $n_F = 2$ , and two real scalars with each having  $n_B = 1$ . It becomes convenient for the mathematics to combine the two real scalars into one complex scalar field. Now the combination of a complex scalar field and a Weyl fermion is known as a chiral supermultiplet.

#### 2.3.2 Minimal Supersymmetric Standard Model

We have discussed how the fermions transform under the rules of SUSY, but how do the scalar field mediators translate into this new framework. First, lets look at the Higgs boson. We know that there is not only one chiral supermultiplet. If there was only one in the electroweak gauge symmetry, with a Higgsino of spin-1/2, would

Names		spin 0	spin $1/2$	$SU(3)_C, SU(2)_L, U(1)_Y$
squarks, quarks	Q	$(\widetilde{u}_L \ \widetilde{d}_L)$	$(u_L \ d_L)$	$({f 3},{f 2},{1\over 6})$
$(\times 3 \text{ families})$	$\overline{u}$	$\widetilde{u}_R^*$	$u_R^\dagger$	$(\overline{f 3},{f 1},-rac{2}{3})$
	$\overline{d}$	$\widetilde{d}_R^*$	$d_R^\dagger$	$(\overline{\bf 3},{\bf 1},{\textstyle {1\over 3}})$
sleptons, leptons	L	$(\widetilde{ u}\ \widetilde{e}_L)$	$( u \;\; e_L)$	$({f 1},{f 2},-{1\over 2})$
$(\times 3 \text{ families})$	$\overline{e}$	$\widetilde{e}_R^*$	$e_R^\dagger$	(1, 1, 1)
Higgs, higgsinos	$H_u$	$(H_u^+ \ H_u^0)$	$(\widetilde{H}_u^+ \ \widetilde{H}_u^0)$	$({f 1},{f 2},+{ extstyle rac{1}{2}})$
	$H_d$	$(H_d^0 \ H_d^-)$	$(\widetilde{H}_d^0 \ \widetilde{H}_d^-)$	$({f 1},{f 2},-{1\over 2})$

Table 2.2: The chiral supermultiplets of the MSSM. Spin-0 fields are complex scalars and spin-1/2 fields are left-handed two component Weyl fermions [3].

Names	spin 1/2	spin 1	$SU(3)_C, SU(2)_L, U(1)_Y$
gluino, gluon	$\widetilde{g}$	g	(8, 1, 0)
winos, W bosons	$\widetilde{W}^{\pm}$ $\widetilde{W}^{0}$	$W^{\pm}$ $W^0$	( <b>1</b> , <b>3</b> , 0)
bino, B boson	$\widetilde{B}^0$	$B^0$	(1,1,0)

Table 2.3: The chiral supermultiplets of the MSSM [3].

not have the anomaly cancellation of the traces,  $Tr[T_3^2Y] \neq 0$  and  $Tr[Y^3] \neq 0$ , where  $T_3$  is the third component of weak isospin and Y is the weak hypercharge. In the SM, the traces of these for the fermions are already satisfied. So we must include two chiral supermultiplets of the Higgsino, with  $Y = \pm \frac{1}{2}$ , see table 2.2.

It turns out that this is also necessary for the Higgsino to give mass to different particles in the SM. A Higgs boson with Y=1/2 has the Yukawa couplings that allow it to interact with the up-type quarks (u,c,t). Only a Higgs boson with Y=-1/2 has the correct Yukawa couplings to interact with the down-type quarks (d,s,b) and the charged leptons  $(e,\mu,\tau)$ .

The SM vector boson will also have a corresponding chiral supermultiplet. They

have fermionic superpartners that are referred to as gauginos. For the  $SU(3)_C$  color gauge interactions of QCD, which are a spin-1/2 color-octet, has a partner called a gluino  $(\tilde{g})$ . The electroweak gauge theory  $SU(2)_L \times U(1)_Y$  has the superpartners  $\widetilde{W}^+, \widetilde{W}^0, \widetilde{W}^-$ , and  $\widetilde{B}^0$  each with spin-1/2, called winos and bino, see table 2.3. The gaugino mixtures of  $\widetilde{W}^0$  and  $\widetilde{B}^0$  give the corresponding zino  $(\widetilde{Z}^0)$  and photino  $(\widetilde{\gamma})$ . The chiral supermultiplets shown in table 2.2 and 2.3 give the particles of the Minimal Supersymmetric Standard Model (MSSM).

The five higgsinos and electroweak gauginos mix with each other to because of electroweak symmetry breaking [3]. The neutral higgsinos  $(\widetilde{H}_u^0 \text{ and } \widetilde{H}_d^0)$  and neutral gauginos  $(\widetilde{B} \text{ and } \widetilde{W}^0)$  mix into four mass eigenstates, which are called neutralinos,  $\widetilde{\chi}_1^0, \widetilde{\chi}_2^0, \widetilde{\chi}_3^0$ , and  $\widetilde{\chi}_4^0$ . The charged higgsinos  $(\widetilde{H}_u^+ \text{ and } \widetilde{H}_d^-)$  and charged gauginos  $(\widetilde{W}^+ \text{ and } \widetilde{W}^-)$  can mix into two mass eigenstates with charge  $\pm 1$  called charginos,  $\widetilde{\chi}_1^{\pm}$  and  $\widetilde{\chi}_2^{\pm}$ .

### 2.3.3 R Parity

R-parity or matter parity is the multiplicatively conserved quantum number defined as,

$$P_R = (-1)^{3(B-L)+2s}, (2.39)$$

where B is the baryon number, L is the lepton number, and s is the spin of the particle. From this we can find the R-parity of all the particles in the SM and MSSM. The definition of R-parity is quite useful because all the particles of the SM have an R-partity of  $P_R = +1$ , while all of the squarks, sleptons, gauginos, and higgsinos have  $P_R = -1$ .

R-parity is thought to be exactly conserved in SUSY, where there is no mixing between particles  $(P_R = +1)$  and sparticles  $(P_R = -1)$ . This leads to three important

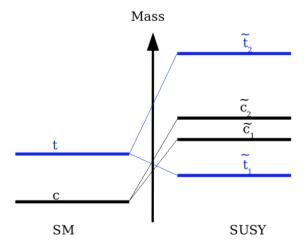

Figure 2.9: On the right we have the arbitrary masses of the top and charm quarks. The left and right handed states mix into two mass eigenstates. It is possible that the top squark will have the smallest mass of the squarks.

#### consequences:

- The lightest sparticle that has  $P_R = -1$  is called the "lightest supersymmetric particle" or LSP, which must be absolutely stable. If it is electrically neutral, it is a possible non-baryonic dark matter candidate.
- Every sparticle, other than the LSP, must eventually decay into an odd number of LSPs.
- For collider experiments, sparticles will only be produced in even numbers.

We are going to be investigating a MSSM that conserves R-parity. This is quite well motivated by the possibility of a dark matter candidate.

#### 2.3.4 Mass Spectrums

The third family of squarks and sleptons should have quite different masses compared to their first- and second-family counterparts, which is caused by the large Yukawa  $(y_t, y_b, y_\tau)$  and soft  $(a_t, a_b, a_\tau)$  couplings, which are holomorphic parameters proportional to the Yukawa couplings. This causes significant mixing between the chiral superpartners  $(\tilde{t}_L, \tilde{t}_R), (\tilde{b}_L. \tilde{b}_R)$ , and  $(\tilde{\tau}_L, \tilde{\tau}_R)$ . We will concentrate on how the mass of the top squark,  $\tilde{t}$  evolves in the MSSM. Given many contributions to the top squark mass such as; squared-mass terms, 4-vertex interactions terms with the uptype Higgs, the 3-vertex interactions with the down-type Higgs, and scalar potential couplings. We have a square-mass matrix for the top squarks,

$$\mathcal{L}_{\text{stop masses}} = -\begin{bmatrix} \tilde{t}_L^* & \tilde{t}_R^* \end{bmatrix} \boldsymbol{m}_{\tilde{t}}^2 \begin{bmatrix} \tilde{t}_L \\ \tilde{t}_R \end{bmatrix}$$
(2.40)

where

$$\boldsymbol{m_{\tilde{t}}^{2}} = \begin{bmatrix} m_{Q_{3}}^{2} + m_{t}^{2} + (\frac{1}{2} - \frac{2}{3}sin^{2}\theta_{W})cos(2\beta)m_{Z}^{2} & v(a_{t}^{*}sin\beta - \mu y_{t}cos\beta) \\ v(a_{t}sin\beta - \mu^{*}y_{t}cos\beta) & m_{\overline{u}_{3}}^{2} + m_{t}^{2} + (\frac{2}{3}sin^{2}\theta_{W})cos(2\beta)m_{Z}^{2} \end{bmatrix}.$$
(2.41)

This is a hermitian matrix and can be diagonalized to give eigenstates  $\tilde{t}_1$  and  $\tilde{t}_2$  which are linear combinations of the left and right-handed  $\tilde{t}$ , see fig. 2.9. Now we get the eigenvalues for the mass states as  $m_{\tilde{t}_1}^2 < m_{\tilde{t}_2}^2$ . From this models predict that the  $\tilde{t}_1$  is the lightest squark [3].

## 2.3.5 Supersymmetry Searches

The SM of particle physics has been a powerful model for predicting interactions between quarks, leptons, and force carriers, with an accurate prediction for precision measurements, but has some faults such as, the Hierarchy problem, dark matter, and a Grand Unified Theory. We have seen that including SUSY can allow for possible solutions, such as: a dark matter candidate as the LSP, bosonic-fermionic loop corrections for the Higgs boson mass, and a unification of the fundamental forces at large energies. Then once investigating the theory of SUSY we were able to determine that the top squark could be the lightest squark, which allows us to develop multiple searches for this proposed theory.

### 2.4 Current SUSY Results

Here we see the most current results from searches for the top squark. These have been completed with data from the first part of Run 2 with 35.9 fb<sup>-1</sup>. This analysis was completed with the most up-to-date identification methods for particles in the SM. From this Analysis, all 104 search region bins, as well as the corresponding single-lepton control region bins, the  $\gamma$ +jets control region bins and the QCD control regions, are fit simultaneously in order to evaluate the cross section excluded at 95% confidence level for each signal benchmark point.

The easiest way to think about the plots shown in 2.10, 2.11, 2.12, 2.13, 2.14, is that there is a calculated limit for each mass point. The x-axis is the possible mass range for the  $\tilde{t}$ ,  $m_{\tilde{t}}$  and the y-axis is the possible range for the  $\tilde{\chi}_1^0$ ,  $m_{\tilde{\chi}_1^0}$ . Each point in this 2D space has a color representation for the value of the upper limit on the cross section at a confidence level of 95%.

With the comprehensive analysis that was performed in 2016, we have various limits on the multiple decay modes of the  $\tilde{t}$  which will be covered completely in Section 5. The comprehensive limits on the  $\tilde{t}$  mass range from values of 550 to 1.1 TeV for all of the all-hadronic decay modes. The CMS Collaboration has also

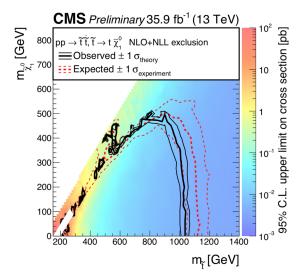

Figure 2.10: Limits for the mass parameter space for T2tt decays. With a current limit of 1.1 TeV for a minimal neutralino mass.

combined the limits from the separate analyses which concentrate on the 1-lep, 2-lep, MT2, and HT missing analyses. The conbination of these has shown that we can set limits on the  $\tilde{t}$  mass range for masses of 800 to 1100 GeV.

From the above plots, 2.10, 2.11, 2.12, 2.13, 2.14, and 2.15, we know that we are able to exclude a large mass range for the  $\tilde{t}$  and  $\tilde{\chi}_1^0$ . Since this is one for a luminosity of 36.8 fb<sup>-1</sup>, we can expect improved limits with all of the data from Run 2, which is 137 fb<sup>-1</sup>. The new version of the analysis also has a redesigned search region to allow for more sensitive results, while also impoving various object definitions.

## 2.5 Improved Methods

Search have been performed on the 36.8 fb<sup>-1</sup> dataset from CMS. We have been able to exclude a mass range of 800 to 1100 GeV from the previous analysis. With the included luminosity and updated analysis methods we expect to significantly

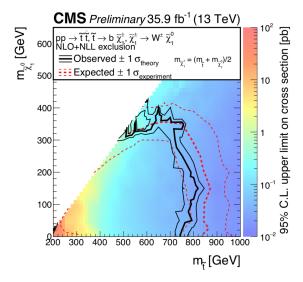

Figure 2.11: Limits for the mass parameter space for T2bW decays. With a current limit of 750 GeV for a minimal neutralino mass.

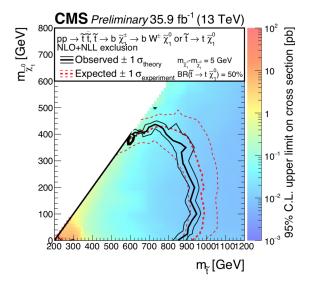

Figure 2.12: Limits for the mass parameter space for T2tb decays. With a current limit of 850 GeV for a minimal neutralino mass.

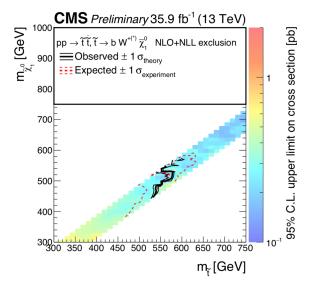

Figure 2.13 : Limits for the mass parameter space for T2fbd decays. Which has a range of 550 GeV for a  $\tilde{\chi}^0_1$  mass of approx. 500 GeV.

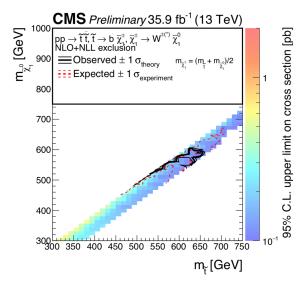

Figure 2.14 : Limits for the mass parameter space for T2bWC decays. Which has a range of 550 to 675 GeV for a  $\tilde{\chi}^0_1$  mass of 600 GeV.

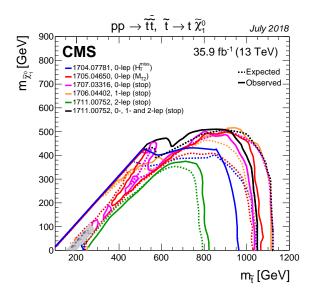

Figure 2.15: Limits for the mass parameter space for T2tt decays using results from all the analysis in CMS. With a current limit of 1.1 TeV for a minimal neutralino mass.

improve these results.

## Chapter 3

## Compact Muon Solenoid

#### 3.1 The Detector

The Compact Muon Solenoid (CMS) is a particle detector as part of the Large Hadron Collider (LHC) which is located near Geneva, Switzerland as part of the CERN collaboration. The CMS detector is 21.6 m long, 15 m diameter, and 14,000 tons and is used to detect many different species of particles. It is separated into layers that, from the interaction vertex outward are, the silicon tracker, Electromagnetic Calorimeter (ECAL), Hadronic Calorimeter (HCAL), superconducting solenoid, and the muon chambers, see Fig. 3.1.

The CMS detector is designed to detect the decay products of most of the particles of the SM, except for neutrinos since they are weakly interacting and will almost certainly pass through the entire earth without an interaction. A defining feature of CMS is the 12.6-m long, 5.9 m inner diameter, 3.8 T superconducting solenoid. This is used to bend the trajectory of charged particles thoughout the detector, such that we can reconstruct the momentum and charge of the particles. The LHC provides a 13 TeV proton-proton beam (4.5 TeV heavy ion) beam with a bunch crossing every 25 ns (50 ns) to produce interaction at luminosities up to  $2.5 \times 10^{34} \text{cm}^{-2} s^{-1}$ .

The coordinate system of CMS has the origin at the nominal collision point in the center of the detector. The y-axis points vertically upward, x-axis points radially inward toward the center of the LHC, and z-axis points along the beam directions

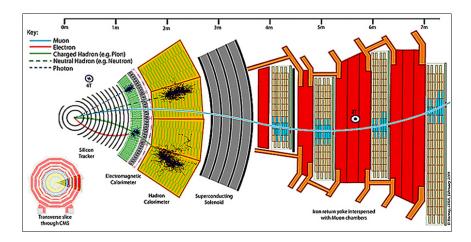

Figure 3.1 : A cross-section of the CMS detector, oriented by looking down the direction of the beam pipe.

towards the Jura mountains from LHC Point 5. The polar angle  $\theta$  is measured from the z-axis and the azimuthal angle  $\phi$  is measured in the x-y plane from the x-axis. The pseudorapidity of a particle is defined as  $\eta = -\ln \tan(\theta/2)$  where  $\theta$  is the angle between the particle momentum and the positive direction of the beam axis, two notable values are  $\eta = 0$  at  $\theta = \pi/2$  and  $\eta = \inf$  at  $\theta = 0$ . Pseudorapidity is quite useful since the difference of pseudorapidities is Lorentz invariant. The transverse components of momentum,  $p_T$ , and energy,  $E_T$ , are computed using the x and y components of the particles.

#### 3.1.1 Tracker

The silicon tracker is made up of two different detectors, the silicon pixels and the silicon strip tracker. This is the inner most detector for CMS and receives the largest flux of particles during operation. This requires it to be radiation hard and operate with a fine granularity.

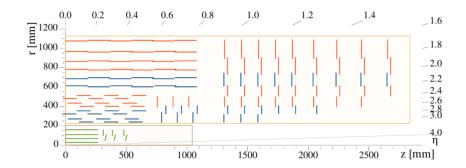

Figure 3.2: Geometry of the CMS Tracker, the inner most region in green is the pixel detector while the outer region in blue and red are the silicon strips.

#### 3.1.1.1 Pixel Detector

The pixel detector was recently upgraded during the winter of 2016/2017. It is approximately 1 m long with four barrel layers ranging from 3.0, 6.8, 10.2, and 16.0 cm from the beam axis and three endcap disks, see fig. 3.2. Since it is the closest detector to the interaction vertex it therefore has the highest particle flux at  $10^7/\text{cm}^2/s$  at r = 10 cm. The resolution is 9.4  $\mu$ m in  $r - \phi$  and 20 – 45  $\mu$ m in z.

The pixel detector contains 1,184 modules in the barrel pixels (BPIX) and 672 modules in the forward pixels (FPIX). The number of individual pixels is 79 (45) million in the BPIX (FPIX) regions, respectively, with a pixel size of  $100 \times 150 \ \mu m^2$ . A pixel module contains two layers, a silicon layer that is bump bonded to 16 Readout Chips (ROCs) which form a module of 66560 pixels, see fig. 3.3. Each unit is controlled with one or more Token Bit Managers (TBMs) which controls the readout of the digital signal from the pixels to the Front-end Driver (FED). For BPIX Layers 3, 4 and all of FPIX there is 1 TBM per module. BPIX layer 2 has 2 TBMs with each one controlling 8 ROCs, while BPIX layer 1 has 4 TBMs with each one controlling 4 ROCs. The information from each module is split into two channels with each

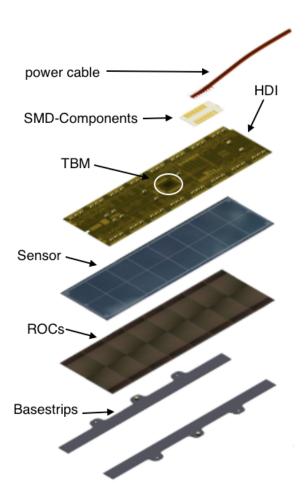

Figure 3.3 : Components of the pixel modules. Made up of a silicon layer, a grid of 8 ROCs which are attached via bump bonds. This is all controlled with a TBM connection to read out data.

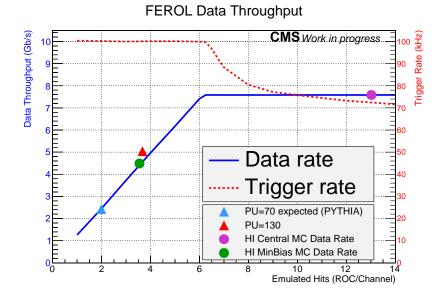

Figure 3.4: Measuring the throughput of the FED with the emulated and simulated events provided by the FED Tester. The Data rate is shown as the solid blue line with the corresponding trigger rate as the dotted red line. The simulated event sizes are shown as their equivalent emulated hits/ROC/channel on the data line.

containing 8, 4, or 2 ROCs. These are encoded together by the TBM before being sent to the FED.

The silicon pixel system is set up as a reverse p-n junction, where the pixels are in the n-type region. As a charged particle travels through the silicon it creates electronhole pairs. A voltage difference is applied to the silicon such that the electrons will deposit onto the pixels. Since the detector is inside of the magnetic field, a lorentz drift will cause the electrons to reach more than one pixel and increase the resolution. As the pixel system continues to be irradiated with large quantities of particles the voltage in the silicon decreases. This will lead to less charge sharing between the pixels and a decrease in resolution of particle locations.

The data, from the pixels, is sent via optical fiber to the FED where is decoded

and processes the information. The FED is responsible for identifying the relevant data, determining possible error states, and packaging the information to be sent to the central Data Acquisition (cDAQ) of CMS. Each of the 108 FEDs, for the pixels, receives 24 independent fibers from the detector. Each of these fibers contains 2 channels from the pixel module. Through robust testing with the FED Tester [Cite here], we have confirmed that the FED is able to attain a maximum data throughput of approximately 7.5 Gbps, see fig. 3.4.

#### 3.1.1.2 Silicon Strips

The silicon strips have a 200 m<sup>2</sup> active region with 15,148 modules that are distributed in 10 barrel layers and 9 + 3 endcap disks. This has a cell size ranging from  $10\text{cm} \times 80~\mu\text{m}$  to  $25\text{cm} \times 180~\mu\text{m}$  since the particle flux decreases further away from the vertex, [MAYBE ANOTHER FIGURE]. It has a resolution of  $23-24~\mu\text{m}$  in  $r-\phi$  and  $23~\mu\text{m}$  in z for the microstrip tracker

How is it different from the pixels?

#### 3.1.2 Electromagnetic Calorimeter

The ECAL is a homogeneous calorimeter made out of 61,200 lead tungstate (PbWO<sub>4</sub>) crystals in the barrel and 7,324 crystals in each endcap. The barrel region has an inner radius of 129 cm and covers a pseudorapidity range of  $0 < |\eta| < 1.479$ . The encaps are 314 cm from the interaction point and cover a range  $1.479 < |\eta| < 3.0$  in pseudorapidity. Lead tungstate was chosen for the crystals since it has a short radiation length,  $X_0 = 0.89$ cm, fast with 80% of the light being emitted within 25 ns, and it's radiation hard. Each crystal in the barrel has a cross-section of  $\approx 22 \times 22$ mm<sup>2</sup> and length of 230 mm, while the endcap crystals are  $28.6 \times 28.6$ mm<sup>2</sup>

and length of 220 mm corresponding to  $25.8X_0$  and  $24.7X_0$ , respectively. An ECAL uses electromagnetic showers to detect particles that interact electromagnetically. Electrons traveling through the material will radiate a photon via bremsstrahlung. A photon will pair produce two electrons. Combining these two processes leads to electromagnetic showers as the particles travel through the detector. The process will continue until a critical energy is reached such that an electron cannot radiate any further and will then lose energy via collisions. The resulting light is recorded by silicon avalanche photodiode (vaccuum phototriodes) in the barrel (endcap).

#### 3.1.3 Hadronic Calorimeter

The HCAL is a hermetic calorimeter consisting of alternating layers of brass as the absorber material and a scintillator. Brass is chosen since it is non-magnetic and has a relatively short interaction length. In the scintillator, a portion of the energy from the hadron in converted into visible light which is then measured by a hybrid photodiode tube to measure the energy. The barrel part of the HCAL consists of 2304 towers that are segmented into  $\Delta \eta \times \Delta \phi = 0.087 \times 0.087$  pieces that cover a region  $0 < |\eta| < 1.4$  in pseudorapidity. The encap region consists of 2304 towers with varying segmentation sizes and a coverage of  $1.3 < |\eta| < 3.0$ .

There are two additional parts of the HCAL to allow for maximum coverage of the detector volume. There is a outer hadron detector that is located outside the superconducting solenoid, which covers a slightly smaller pseudorapidity range as the barrel region. They serve as a tail catcher for hadron showers that penetrate all the way through the inner HCAL and solenoid. A forward hadron calorimeter, located 11.2 m from the interaction point covering a pseudorapidity  $3.0 < \eta < 5.0$ , made out of steel/quartz fiber is specifically designed for the columnated Cerenkov

light in this region.

#### 3.1.4 Superconducting solenoid

Surrounding most of this is the superconducting solenoid which is 12.6 m long with a 5.9 m radius. The field strength is 3.8 T which has a stored energy of approximately 2.7 GJ. The magnet is designed such that a muon with momentum, p = 1 TeV, will have a momentum resolution of  $\Delta p/p \approx 10\%$ . The solenoid is a high-purity aluminium-stabilized conductor, which is a similar material used in other large solenoids.

#### 3.1.5 Muon Chambers

The muon system has three main detection systems that are used to identify a muon candidate. In the barrel region, drift tube (DT) chambers are used since the neutron background, muon rate, and magnetic field are all small. In the endcaps, cathode strip chambers (CSCs) are used since the relative values stated before are much larger. Included throughout the whole system are resistive plate chambers (RPC).

The DT consists on 250 chambers in 4 barrel layers at a radii of 4.0, 4.9, 5.9, and 7.0 m from the beam axis. A DT chamber is an array of anode wires in a gaseous medium where the walls are cathodes. A muon passing through the gas will ionize some atoms which are then forced towards the anode wires by the electric field. The drift time of the electrons can then be calculated to within a couple of ns such that a good spatial resolution is achieved. The maximum designed drift length is 2.0 cm. Each station of the DT will give muon vector for each candidate with a  $\phi$  precision of 100  $\mu$ m in postion and 1 mrad in direction.

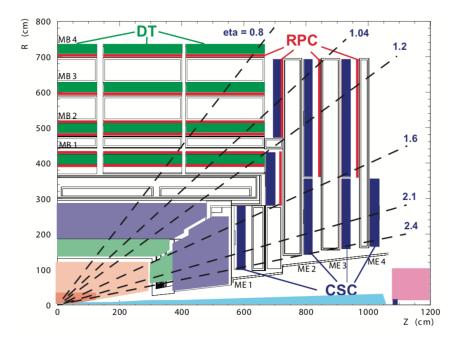

Figure 3.5: A quarter cross-section of the three muon detection systems for CMS.

The CSC system uses the same concept as the DT system, but also includes a measurement of the ions that follow the electric field to the cathode strips. In this system the anode wires and the cathode strips are perpendicular so the collected charge on both provide a accurate position measurement.

The RPC system contains two parallel plates, anode and cathode, the charge is measured by external metallic strips that can quickly measure the momentum of a muon and decide if the event should be triggered.

### 3.2 Detector Methods

Using the objects and information from each of the subdetectors we can measure the important information required for the  $\tilde{t}$  search. Since the search is dependent

on large missing energies it is dependent on measuring all forms of energy in the standard model and checking for any inefficiencies.

## Chapter 4

## Search Strategy

## 4.1 Physics Objects

There are many different types of physics objects that we are interested in when working with particle physics experiments. Since the particles that we are interested in have very short lifetimes,  $\mathcal{O}(\text{decay}) = 10^{-23}$  s, we mainly interact with the decay products of the event, such as, jets, heavy object tagging, particle identification, missing transverse momentum  $\cancel{E}_T$ , sum scalar jet momentum  $H_T$ , number of secondary vertices  $N_{SV}$ ,  $p_T^b$ , soft b-tagging, transverse mass between tagged b quarks  $m_T(b_{1,2},\cancel{E}_T)$ , Initial State Radiation, and lepton identification.

NEEDS MORE SPECIFICS ON JETS IDS AND B JET CSVs

#### 4.1.1 Jets

In an interaction, because of color confinement, whenever a quark is made it must come in pairs (q, q') such that the total color charge of the interaction is neutral. Typically due to conservation of momentum the quarks may originally be produced near the interaction point but will quickly start to move away from each other. Eventually the quarks will move far enough apart and will have enough potential energy in the gluon connections between them that it is now more efficient to create a new quark-antiquark  $(q\overline{q})$  pair. This will continue to occur in a sequence of radiating gluons and producing new pairs of charged particles. In the final state, the energy

deposited in the HCAL is due to a cluster of charged particles of a certain radius,  $\Delta R = \sqrt{\Delta \eta^2 + \Delta \phi^2}$ . There are many algorithms to reconstruct the jets, we are mainly interested in the anti-kT Jet algorithm [reference] method which uses the transverse momentum of the particles within a certain radius  $\Delta R = 0.4(0.8)$  for AK4(AK8) jets.

#### 4.1.2 Heavy Object Tagging

Since this search is looking for a massive particle which then decays to slightly less massive particles we need to be able to identify and distinguish between them. Firstly, b-tagged jets which are jets that are likely to have originated from a b quark. These are identified reconstructing where the jet originated from and comparing the distance away from the interaction point. A b quark is a relatively long-lived particle and can travel many millimeters before decaying. Since we have a resolution of  $\mu$ m this is not a problem. For b quarks with large transverse momentum, we use a Combined Secondary Vertex (CSVv2/DeepCSV) algorithm depending on the year the data was taken.

#### 4.1.3 B-Tagging

B-tagged jets are identified using the Run 2 version of the Deep Combined Secondary Vertex (DeepCSV) algorithm. The medium working point recommended by the B-tag POG, corresponding to a threshold of 0.6324m 0.4941, and 0.4184 for the 2016, 2017, and 2018 on the DeepCSV, is used for the b-jets for this analysis.

#### 4.1.4 Missing Transverse Momentum

The missing transverse momentum is the negative vector sum of the total transverse momentum measured in the detector,

$$\cancel{E}_T = -\sum_{i \in \text{vis}} \overrightarrow{p}_{i,T}, \tag{4.1}$$

where the momentum runs over every visible(vis) particle in the event. Ideally, if the detector was 100% this quantity would always be zero due to conservation of momentum, but many things, such as detector efficiency, paticles that are weakly interacting, or particles beyond the SM will cause the missing energy. Because of these, this object is a good discriminator for searching for physics beyond the SM.

### 4.1.5 MET Filters

#### **4.1.6** $H_T$

Another interesting quantity is  $H_T$ , which is the scalar sum of the  $p_T$  of all of the jets in an event,

$$H_T = \sum_{i \in \text{jets}} p_{i,T}. \tag{4.2}$$

This quantity is quite useful when trying to identify massive particles, which are much more massive than the average particle.

#### 4.1.7 Secondary Vetices

The ability to identify secondary vertices is essential for search for the top squark. In searches for the top squark, one of the main decay is to a bottom quark, b, and

a neutralino,  $\tilde{\chi}_1^0$ . Since the b quark is a long lived particle, about 10-12 seconds, that will travel many mm before decaying into other particles. The tracks from the charged particles will cause tracks in the various detectors of CMS. These tracks are defined by hits that are then reconstructed using multiple algorithms which can reconstruct the paths of the particles through the detector. Once the tracks are reconstructed, we can backtrack to a point where the particle originated from and then identify is flavor. When we reconstruct a particles to a point that is displaced from the primary vertex it is known as a secondary vertex and has the potential to be an long lived particle.

#### 4.1.8 B Quark Transverse Momentum

Initial-state radiation (ISR) may be clustered into one of the large-R jets clustered with a distance parameter of 0.8. We use the larger radius jets to be sensitive to ISR with gluon splitting, when a jet radiates a qluon that pair produces two quarks. The ISR jet is identified as being the hardest of the large-R jets with  $p_T > 200$  GeV which fails the loose b-tagging working point and is not identified as a top or W.

#### 4.1.9 Soft b-tagging

This search targets also models that produce very soft bottom or charm quarks. A typical  $p_T$  spectrum of the b quarks in three T2fbd signal models is shown in fig. . A large fraction of events contain b quarks with  $p_T$  below the 20 GeV jet- $p_T$  threshold which may thus fail to be reconstructed as jets or become b-tagged. Identification of these soft quarks improves our ability to separate potential signal events from the SM background. We therefore aim to identify b/c quarks based on the presence of a secondary vertex (SV) reconstructed using the Inclusive Vertex Finder (IVF)

algorithm. Additional requirements on SV observables are applied to suppress the background originating from light quarks. These selected SV may be referred to as soft b tags and are constructed to be orthogonal to the jets and b-tagged jet used in this analysis.

The requirements on each SV to pass the soft b-tagging definition are:

- The distance in the transverse plane between the SV and the PV is less than 3 cm.
- The significance of the distance, SIP3D, between the SV and the PV is greater than 4.
- The pointing angle, defined as  $cos(\overrightarrow{PV},\overrightarrow{SV},\overrightarrow{p}_{SV})$ , is greater than 0.98, where  $\overrightarrow{p}_{SV}$  is the total four-momentum of the tracks associated to the SV.
- The number of tracks associated to the SV is greater or equal to 3.
- The  $p_T$  of the SV is less than 20 GeV.
- The distance to any jet,  $\Delta R(\text{jet}, \overrightarrow{p}_{SV})$ , is greater than 0.4 to achieve the orthogonality to the jets and b-tagged jets.

This definition leads to  $\approx 50\%$  efficiency to identify a soft b/c quark, for  $\approx 3\%$  fake rate.

#### 4.1.10 Lepton Identification

There are two sets of selection criteria used in the analysis for electrons and muons. A set of veto criteria are used to efficiently reject events with an isolated electron of muon in the search region, while more stringent requirements are imposed in some control regions that require high purity samples of isolated leptons.

	Veto W	orking Point	Mediun	n Working Point
	Barrel	Endcap	Barrel	Endcap
$\sigma_{i\eta i\eta}(\text{full}5 \times 5) <$	0.0114	0.0352	0.0101	0.0283
$ \Delta\eta_{ m in}  <$	0.0152	0.0113	0.0103	0.00733
$ \Delta\phi_{ m in}  <$	0.216	0.237	0.0336	0.114
$\frac{h}{E}$ <	0.181	0.116	0.0876	0.0678
$\frac{1}{E} - \frac{1}{p} <$	0.207	0.174	0.0174	0.0898
$ d_0 $ <	0.0564	0.222	0.0118	0.0739
$ d_z  <$	0.472	0.921	0.373	0.602
$N(\text{expected missing inner hits}) \leq$	2	3	2	1
Conversion veto	pass	pass	pass	pass

Table 4.1: Electron identification requirements, defined separately for electrons in the ECAL barrel and endcap regions. The tabulated numbers for each working point are the thresholds applied to the corresponding quantities in the first column.

Electron candidates are identified via a set of selection criteria established by the EGamma POG based on "Spring16" simulated samples in the 25ns bunch spacing scenario. The corresponding thresholds imposed on relevant variables are summarized in Table . The "Veto" working point is used to keep events with electrons out of the final search region. The "Medium" working point is used for the selection of leptonic control regions.

The loose muon definition recommended by the Muon POG is used for the purposes of the muon veto. A loose muon is identified as a PF muon and can be either a global muon or an arbitrated tracker muon. Only candidates with transverse (longitudinal) impact parameter  $|d_0| < 0.2$  cm ( $|d_z| < 0.5$ cm,) with respect to the primary vertex, are considered. The muon selection in leptonic control regions relies on the medium working point defined by the Muon POG for higher purity. The medium muon requirements are summarized in Table . They are applied in addition to the loose muon requirements. Selected muons are required to have transverse (longitu-

Table 4.2: The requirements for a particle trajectory to be tagged as a muon.

dinal) impact parameters  $|d_0| < 0.05$  cm ( $|d_z| < 0.1$ cm), with respect to the primary vertex.

The isolation requirements used in the selection of electrons and muons aim to achieve a high efficiency for correctly identifying events that contain prompt leptons (i.e. leptons that do not originate from heavy flavor decays) in the boosted topologies and busy hadronic environments that are typical for this analysis. They are based on the mini-isolation quantity, which is a measure of the lepton's local isolation. Mini-isolation is computed as the summed  $p_T$  of PF candidates within a  $\Delta R$  cone centered on the lepton candidate. The cone size depends on the lepton  $p_T$  as indicated in Table and is intended to be small enought to reduce overlaps with jets in the event while also being large enough to contain the products of leptonic b-decays. Higher values of instantaneous luminosity result in a reduced efficiency for the isolation requirement due to an increase in the number of particles originating from additional (pileup) interactions that enter the isolation cone. In order to minimize this effect, the calculated isolation quantity is corrected for the estimated contribution from pileup particles. The correction is applied by subtracting the product of the estimated

average pileup density  $(\rho)$  in the event with an effective area,  $A_{eff}$ , related to the geometrical size of the isolation cone. The residual dependence of the isolation quantity on  $\rho$  for a given cone size is accounted for in  $A_{eff}$ , which is determined by taking the slope of a linear fit to the uncorrected isolation as a function of  $\rho$ . The correction factor is  $\eta$ -dependent, and calibrated separately for charged particles, neutral hadrons, and photons contributing to the isolation.

Electrons and muons are considered to fulfill the veto isolation criteria if their mini-isolation is less than 0.1 or 0.2 respectively, relative to the lepton  $p_T$ . The same thresholds are applied on the relative mini-isolation for electrons and muons in control samples.

#### 4.1.11 Tau Identification

The Tau ID has been studied extensively. After multiple studies which looked into the custum MVA similar to the one used in [], the IsoTrack methods, and Tau POG MVA method of Identifying Taus. The methods which provide the best improvement to the efficiency of identifying taus with a small fake rate is the combination of IsoTrack and Tau POG MVA. With the inclusion of the combined method for identifying hadronically decaying taus the efficiency should improve greatly.

## 4.2 Search Strategy

#### 4.2.1 Trigger

#### 4.2.2 Baseline Selection

Following the same methods as above, we have a loose pre-selection which is referred to as the baseline selection. This will place a selection on jets and  $E_T$  which

is used to eliminate a large fraction of background events. We define the baseline selection as:

- $N_{e,(\mu)} = 0, (p_T > 5GeV, |\eta| < 2.5(2.4))$
- $N_{iso} = 0, (p_T > 5(10)GeV, ISO < 0.2(0.1)$  for electron/muons(pions))
- $N_{tay} = 0, (p_T > 20 GeV, |\eta| < 2.4)$
- $N_i \ge 2, (p_T > 20 GeV, |\eta| < 2.4)$
- $E_T > 250$  GeV, to reach the plateau of the trigger efficiency

In Addition to this, we allow for two separte sets of additional selections to apply to the low and high  $\Delta m$  search regions to further reduce background. The high  $\Delta m$ baseline selection includes the baseline selection and additionally,

- $N_i \ge 5, (p_T > 20 GeV, |\eta| < 2.4)$
- $N_b \ge 1, (p_T > 20 GeV, |\eta| < 2.4)$
- Min[ $|\Delta\phi(\cancel{E}_T, j_1)|$ ,  $|\Delta\phi(\cancel{E}_T, j_2)|$ ,  $|\Delta\phi(\cancel{E}_T, j_3)|$ ,  $|\Delta\phi(\cancel{E}_T, j_4)|$ ]  $\equiv \Delta\phi_{1234} > 0.5$ , where  $j_1, j_2, j_3, j_4$  are the four leading jets in  $p_T$ . This requirement is to reduce the QCD multijet background.

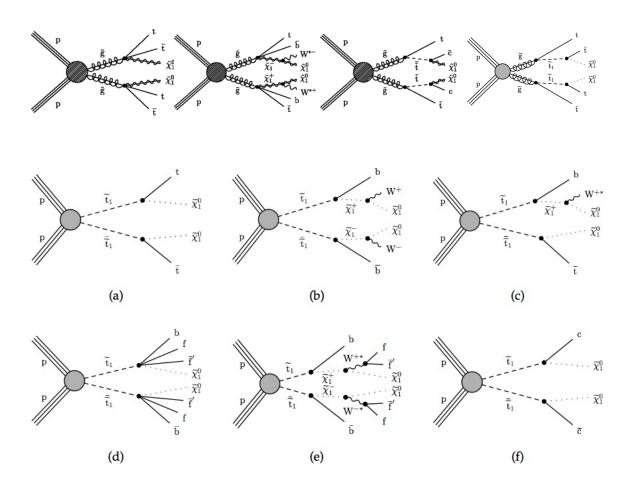

Next, the low  $\Delta m$  baseline selection has the following addition selections,

- $N_t = 0, N_W = 0, N_{res} = 0$ , where  $N_t$  and  $N_W$  are the number of merged tops and W's, respectively, and  $N_{res}$  is the number of resolved tops
- An ISR jet is defined in Sec. BLANK with  $p_T(ISR) > 200 GeV$ ,  $|\eta| < 2.4$ ,  $|\Delta \phi(j_{ISR}, \cancel{E}_T)| > 2$ .

- $E_T/\sqrt{H_T} \equiv S_{E_T} > 10$ , where  $H_T$  is calculated as the scalar sum of the  $p_T$  of jets with  $p_T > 20 GeV$  and  $|\eta| < 2.4$ .
- $|\Delta \phi(E_T, j_1)| > 0.5, |\Delta \phi(E_T, j_{2,3})| > 0.15$ , where  $j_1, j_2, j_3$  are the three leading jets in  $p_T$ .

Chapter 5

# Stop quark Production and Backgrounds

# 5.1 Production and Decay Modes

Gluon fusion.

Main decay mode mode  $\widetilde{t} \to t + \widetilde{\chi}_1^0$ ,  $\widetilde{t} \to b + \widetilde{\chi}^+$ . The top quark most likely decays into a b quark and W boson.

### 5.2 Standard Model Background

Signal events can be mimicked by SM events that have a large number of jets and missing energy.

Broken up into four major backgrounds, Lost Lepton (LL), Znunu, QCD, Rare decays

#### 5.2.1 Lost Lepton

The contribution from the  $t\bar{t}$  and  $W+{\rm jets}$  processes arises from leptonic decays of the Wboson where the charged lepton is outside the kinematic acceptance of CMS or evades identification by the dedicated lepton vetoes. Large  $E_T$  can be generated by the associated neutrino and the lepton that is not reconstructed, allowing such events to enter the search regions. This background is collectively referred to as the "Lost Lepton" (LL) background. Contributions arising from ttW and single-top processes also enter into this category, but with much smaller importance.

Studies in simulation indicate that the event kinematics for different lepton flavors are similar enough to allow us to estimate them collectively from a single control sample in data that has event characteristics similar to those of the search sample. Because of this, we use the single-lepton control sample to estimate the LL background, using the method descrived in detail in Ref. [18]. The single-lepton sample consists of events that have one lepton satisfying the lepton-veto criteria. In order to suppress potential signal contamination, we require  $M_T(l, E_T) < 100 GeV$ . If there is more than one selected lepton, we randomly select which lepton is chosen to deter-

mine the  $M_T(l, \cancel{E}_T)$ . The requirement of low  $M_T(l, \cancel{E}_T)$  also ensures orthogonality to the search regions used in the search for direct top squark production in the single-lepton final state, making it possible to statistically combine the results of the two searches. The selection applied to the single-lepton control sample follows the same selection on the search variables as in the zero-lepton selection with the exception of classification according to the number of top and W-tagged candidates.

#### 5.2.1.1 Transfer Factors

The LL estimation in each search region is based upon the event count in data in the corresponding control region in the single-lepton sample. The count is extrapolated to the search region to obtain a prediction by means of a transfer factor obtained from simulation samples as follows:

$$N_{vred}^{LL} = TF_{LL} \cdot N_{data}(1l). \tag{5.1}$$

We want to suppress signal contamination by requiring  $M_T(l, \cancel{E}_T) < 100$  GeV. This requirement confirms that it is orthogonal to the search reagions that are used in the search for direct top squark production in the single-lepton final state. Letting the two analysis statistically combine the results in the future.

This allows us to have the same selection for the single-lepton control sample and the zero-lepton sample. The only exception is the number of top and W-tagged candidates? what is the difference between a candidate and a particle?

The LL estimation is dependent on the yield of data in the corresponding CR and the TF calculated by the single-lepton sample. The transfer factor is defined as,

$$TF_{LL} = \frac{N_{MC}(0l)}{N_{MC}(1l)},$$
 (5.2)

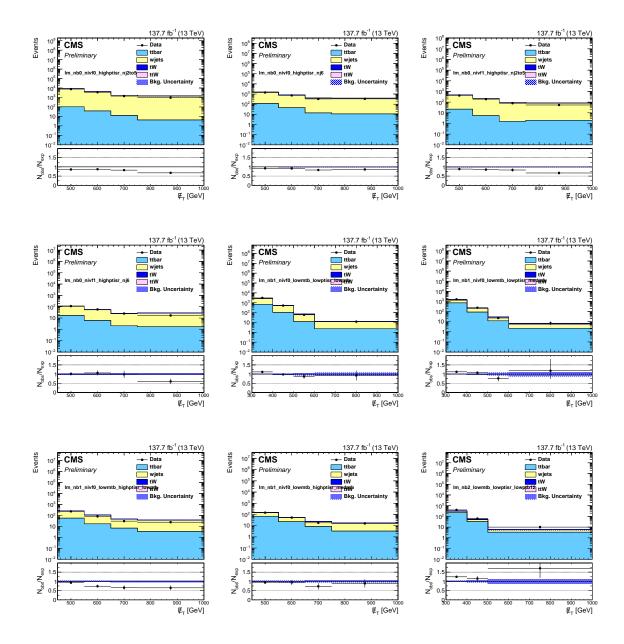

where  $N_{MC}(1l)$  is the event count observed in the corresponding CR and  $N_{MC}(0l)$  use the event count in the corresponding SR.

### 5.2.2 Z Boson Decay to Neutrinos

Znunu: production of a Z boson that decays into two nuetrinos which are then missed by the detector. Can have jets from other quarks/gluons in the interaction

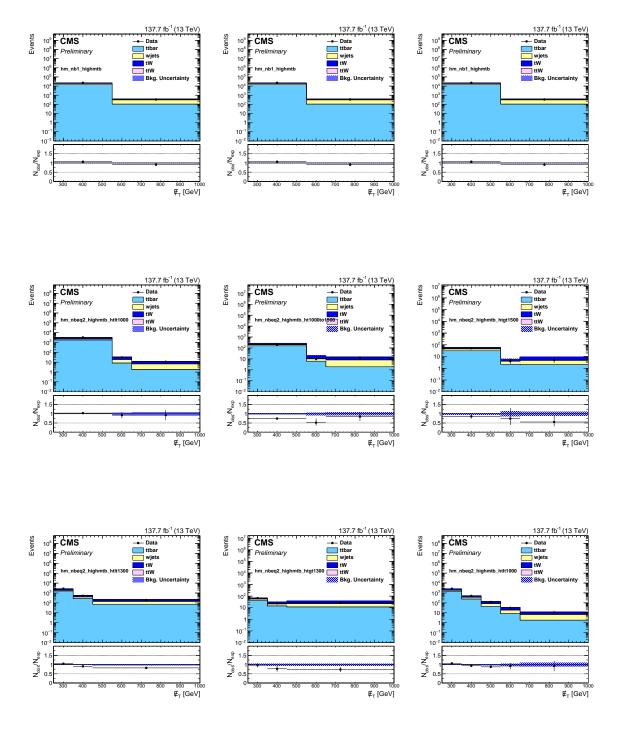

## 5.2.3 Quantum Chromodynamic Events

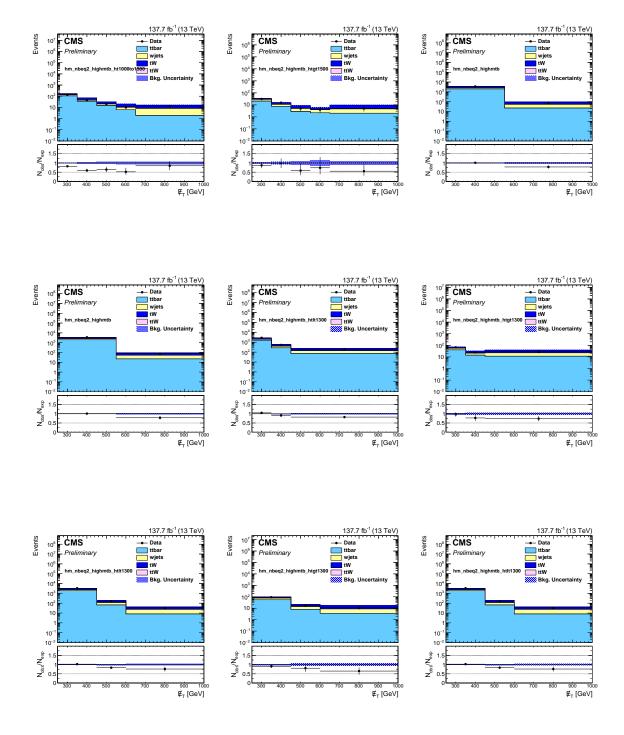

QCD: Events that of jets produced by QCD processes. The missing energy from from a mismeasurement of the jets in the event causing missing energy

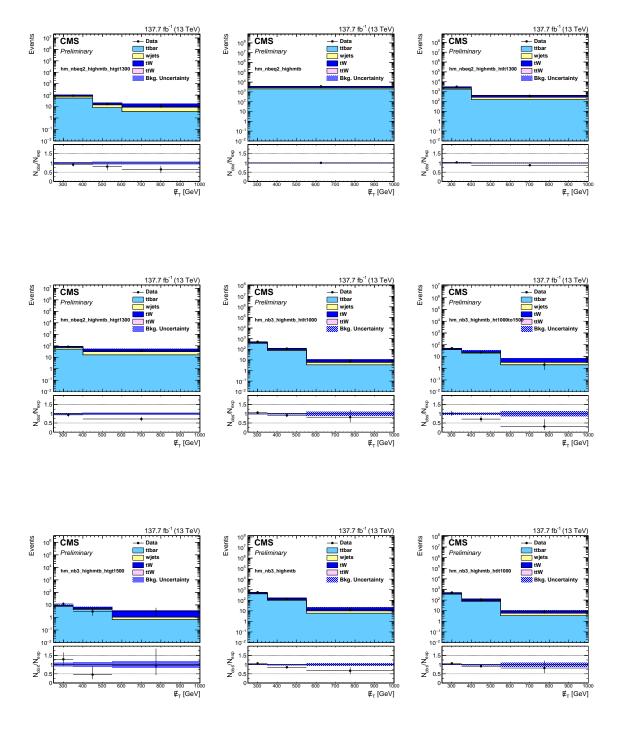

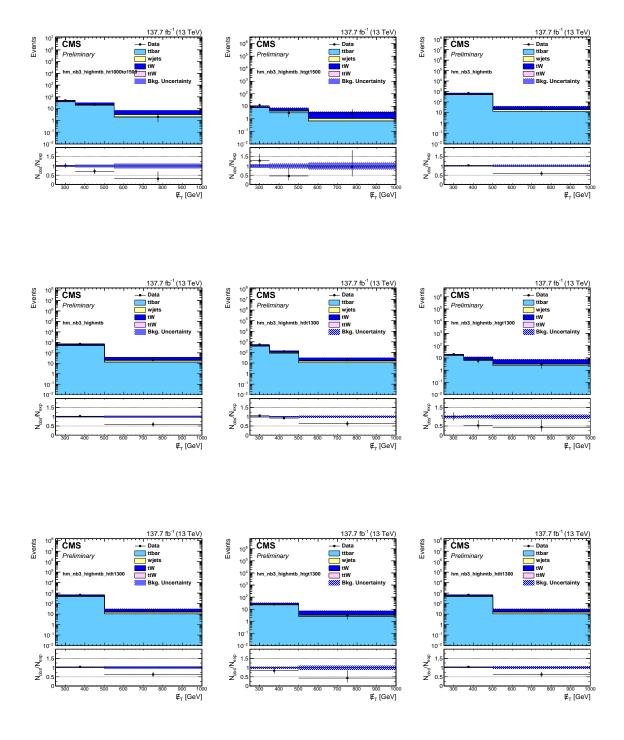

### 5.2.4 Rare Interactions

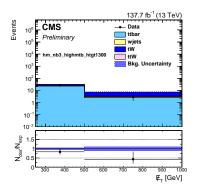

ttZ, ttH, WW, WZ, ZZ, tZq, tWZ: rare processed that can have jets plus MET. Expand upon these later

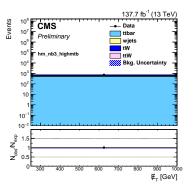

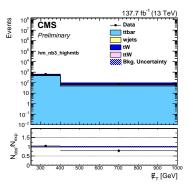

## Chapter 6

## Search Region Design

Using MC simulations that model the SM background for this process we want to reduce the number of events in our Search region. This is an all hadronic search so we are looking at event with zero tagged leptons. Unfortunately, some can get in by not passing the kinematic cuts or just by the non 100 % of the detector. There is a small nonzero inefficiency of mistagging a lepton as something else.

## 6.1 Minimizing the ttZ background

For the ttZ interactions, we produce two top quarks that can then decay to two b quarks and two W bosons. A possible way to mimick our search region is two have multiple jets, i.e. b quarks that hadronize and W bosons that decay hadronically, but we also need missing energy. This will be in addition to the Z boson decaying into two neutrinos and thus creating a large amount of missing energy.

We now try to look at the differing kinematic structure of the background, ttZ, and the signal region, stop quarks decaying. Under the assumption that the Z boson is created by radiated from the top quark the resulting decay to neutrinos should be close, small  $\Delta \phi$ , between the resulting jets. For the signal, the missing energy is produced by the neutralino. When the stop quark decays into top quark and neutralino the top quark should recoil off of neutralino to essentially be back-to-back. This will cause a large angle,  $\Delta \phi$ , between them. We then want to use the

kinematic variable,  $\Delta \phi(t_{1,2}, \cancel{E}_T)$ , where

## 6.2 Lost Lepton Application

Can we apply this to other backgrounds. For boosted tops the the missing energy caused by missing the lepton in the W boson decay. The variable  $\Delta \phi(t_{1,2}, E_T)$  should also apply. Should work for wjts, tW, ttW.

## 6.3 Search Regions

The HM and LM Search regions should be defined and explained. Why are they defined the way they are?

### 6.4 Search Region Optimization

Look for an optimized cust for  $\Delta\phi(t_{1,2}, E_T)$  to maximize  $\frac{S}{\sqrt{B}}$  in each SR. Could have a different cut for each region, but a combination to make it all the same would be nice. Since the signal can decay in multiple ways we need to optimize for all possible scenarios. Explain why we are maximizing  $\frac{S}{\sqrt{B}}$ 

### 6.5 Limits

Looking at the significance and limits for the mass regions of the stop quark decay. Using the Higgs Combined tool, which includes statistics with a "maximal likelihood" fit? The cut,  $\Delta \phi(t_{1,2}, E_T)$ , would hopefully improve the values, but an optimized cut has not been chosen yet.
